Evidence from DNA sequences on the phylogenetic systematics of primates is congruent with the evidence from morphology in grouping Cercopithecoidea (Old World monkeys) and Hominoidea (apes and humans) into Catarrhini, Catarrhini and Platyrrhini (ceboids or New World monkeys) into Anthropeoidea, Lemuriformes and Lorisiformes into Strepsirhini, and Anthropeoidea, Tarsioidea, and Strepsirhini into Primates.

Molecular evidence indicates that the lineage of gibbons (family Hylobatidae) diverged from Great Apes some 18-12 million years ago, and that of orangutans (subfamily Ponginae) diverged from the other Great Apes at about 12 million years; there are no fossils that clearly document the ancestry of gibbons, which may have originated in a so-far-unknown South East Asian hominoid population, but fossil proto-orangutans may be represented by Sivapithecus from India and Griphopithecus from ...

The fossil, informally called "Toumai," is a mosaic of primitive and evolved characteristics, and it is unclear how this fossil fits with the picture given by molecular data, namely that the line leading to modern humans and modern chimpanzees apparently bifurcated about 6 million years ago.

In this study, we have investigated the molecular evolution and organization of centromeric satellites in a basal primate species, the Aye-Aye. The sequence classification and chromosomal distribution of alpha satellite have been widely investigated in primate genomes (Maio et al. 1981 ; Haaf and Willard 1998 ; Willard 1998 ; Rudd and Willard 2004 ; Alkan et al. 2007 ; Cellamare et al. 2009).

Molecular evolution of primates - featuring mobile elements

The genomes of modern humans are riddled with thousands of endogenous retroviruses (HERVs), the proviral remnants of ancient viral infections of the primate lineage. Most HERVs are nonfunctional, selectively neutral loci. This fact, coupled with their sheer abundance in primate genomes, makes HERVs ideal for exploitation as phylogenetic markers. Endogenous retroviruses (ERVs) provide phylogenetic information in two ways: (i) by comparison of integration site polymorphism and (ii) by ...

Interestingly, around 53% of the orphan genes contain sequences derived from transposable elements (TEs) and are mostly located in primate-specific genomic regions. This indicates frequent recruitment of TEs as part of novel genes.

During ~80 million years of primate evolution this process generated ~40% of the human genome where L1 remains active. Thus, accounting for the persistence of L1 is a major issue. Emergent L1 families are often associated with episodes of extensive amino substitutions in the L1 encoded ORF1p protein, which is required for L1 replication.

Phylogenetic analyses carried out on cytochrome c oxidase (COX) subunit I mitochondrial genes from 14 primates representing the major branches of the order and four outgroup nonprimate eutherians revealed that transversions and amino acid replacements (i.e., the more slowly occurring sequence changes) contained lower levels of homoplasy and thus provided more accurate information on cladistic relationships than transitions (i.e., the more rapidly occurring sequence changes).

This Molecular Sequences & Primate Evolution: Amino Acids, Hemoglobins in Evolution Lesson Plan is suitable for 10th - 12th Grade. Students compare differences in amino acids in the beta hemoglobin from representative primates, complete a matrix of those differences, and from these data, construct and interpret cladograms as they reflect relationships and timing of divergence.

Introduction. The deposition of methylation on DNA is a deeply conserved process. In mammals, it is crucial for genome stability, development, genomic imprinting, and chromosome-wide epigenetic silencing such as X-inactivation (Smith and Meissner 2013). Mammalian DNA methyltransferases (DNMTs) are enzymes that catalyze the addition of a methyl group onto cytosines (C).

Although we find that substitution rates vary significantly across MSX1 exons, comparisons of nonsynonymous and synonymous substitution rates (dN/dS) suggest that, as a whole, MSX1 and PAX9 amino acid sequences have been under functional constraint throughout primate evolution. Compared to all other primates in our sample, our analysis of exon 1 in MSX1 finds an unusual pattern of amino acid substitution for Tarsius syrichta, a member of a lineage (tarsiers) that has many unique features ...

Ancestral URAT1 sequences were computationally inferred and ancient transporters were resurrected and assayed, revealing that affinity for uric acid was increased during the evolution of primates. This molecular fine-tuning occurred between the origins of simians and their diversification into New- and Old-World monkey and ape lineages.

For example, the 104 amino acid sequence for mammalian cytochrome c is identical in humans, chimpanzees, gorillas, orangutans and gibbons. The common ancestor for these species existed so recently in the past that no cytochrome c substitutions have become fixed in any of its descendants.
